
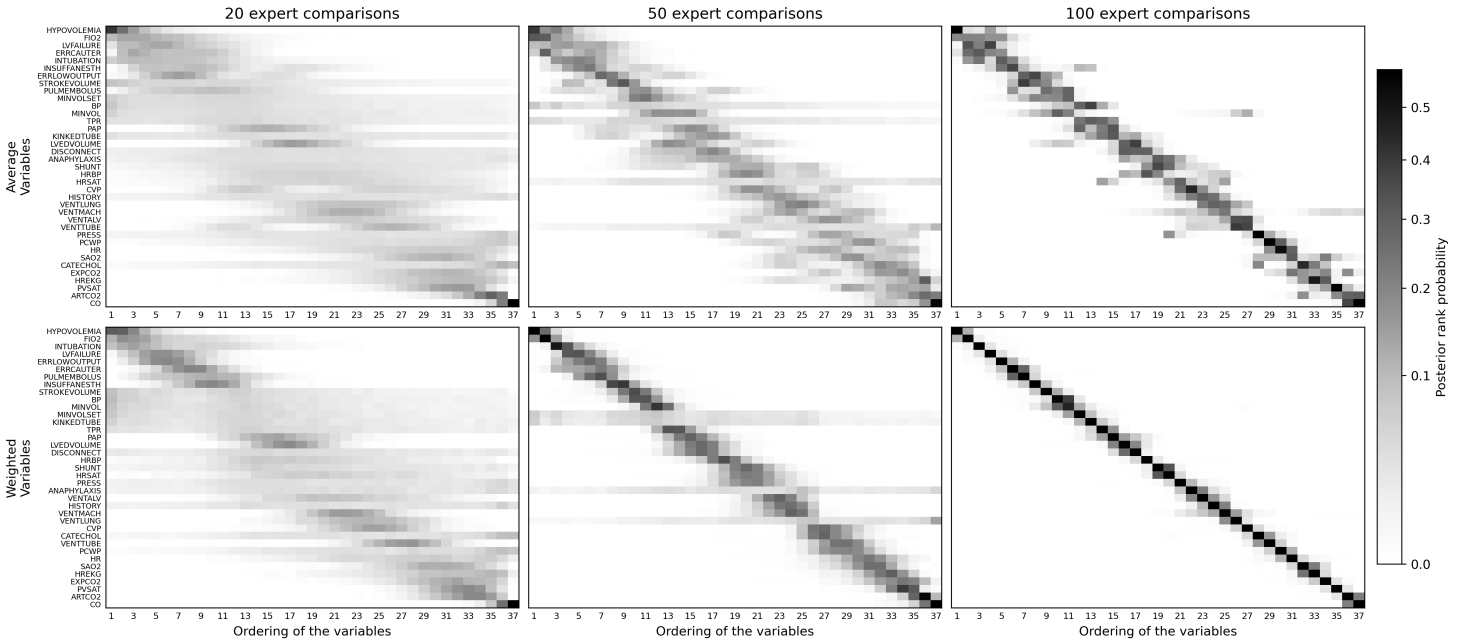

Figure 1: Uncertainty of the causal ordering under two aggregation schemes for expert comparisons from five experts (ordered by accuracy from high to low: one good expert, three moderate-quality experts, and one poor expert) in the Alarm network ($N = 37$). The top row shows results under simple average aggregation, whereas the bottom row shows results under inverse-variance-weighted aggregation, which assigns larger weight to higher-accuracy experts and smaller weight to lower-accuracy experts. From left to right, the panels correspond to 20, 50, and 100 expert comparisons, respectively. Darker shades indicate higher posterior rank probability. The rows correspond to variables, and the x-axis indicates the ordering positions of the variables.
